

ABSTRACT

5 Selective edge softening and selective edge dithering is introduced into
an image representation to improve local control where halo problems are
expected. Selective areas of dilation are isolated and separately dithered or
halftoned, the result of which is then swapped back into or substituted for the
stored original image. In this manner misregistration and color plane-to-plane
interactions can be compensated for in plural image forming station architecture
systems. The same technique is also valuable in monochrome systems as an aid
10 to overcoming edge displacement and slow toner problems when the selective
edge softening is selectively applied to edges which are in particular
perpendicular to the fast scan direction.
